Abstract

A magnesium fertiliser trial was carried out on autumn and early winter sown wheat at three sites near Methven in 2000-01. Treatments included different rates of magnesium oxide or kieserite (magnesium sulphate) applied in early winter, a single rate of these applied in spring and a spray treatment of Magflo (magnesium oxide suspension). Herbage Mg levels were measured twice in the spring and varied considerably between sites and samplings. Spring herbage Mg content increased with increasing rate of winter-applied kieserite in four of the six herbage samplings. Magnesium oxide applied in early winter was not as effective as kieserite in increasing herbage Mg levels. Magnesium applied in the spring was not effective in increasing herbage Mg levels 7-8 weeks later, irrespective of the form of application. There was no significant effect of magnesium treatment on grain yield, grain weight, screenings or grain N or Mg content, despite all sites having low soil Mg levels, and at some stage in the spring, low herbage Mg levels. It is likely that climatic conditions impacted significantly on the results as in the past leaf symptoms of Mg deficiency have been noted at higher soil Mg levels.

Additional key words: autumn sowing, kieserite, magnesium oxide, herbage analysis, grain yield, grain quality

Introduction

Soils in the predominant cropping regions of New Zealand have medium to high levels of exchangeable magnesium and medium to high reserves of magnesium (Metson and Brooks, 1975). Hence historically magnesium has not been seen as a major problem in these areas. However, in Mid Canterbury it is not uncommon to find MAF quick test Mg (QTMg) levels <10, especially near Methven where they can be as low as 4. It is known that pasture dry matter responses are likely at QTMg <5 (Edmeades, 1999). While no soil data are available for crop responses to magnesium in New Zealand, ADAS in Britain consider soils to be deficient at <25 mg/l available Mg (approx QTMg of 4-5), although cereals may not respond until they get to 15 mg/l (Archer, 1988). In New Zealand it is current practice to aim for QTMg >10 for arable crops and 20-30 for vegetable crops. Herbage magnesium levels are considered low at <0.15% (Reuter and Robinson, 1998), although recent local

data would suggest these are now set too high. Typical New Zealand wheat crops usually contain 0.11-0.12% (Craighead, 1999).

Mid Canterbury is the major cropping district in New Zealand and it is not unreasonable to suggest soil magnesium levels are low because of continuous crop removal and farm management practices. Cereals typically remove 5-13 kg Mg/ha depending on the crops grown. Higher yields, increasing N use, specialist seed and process crops, increasing cropping intensity and the extra demands from winter grazing of cattle suggest these values are now conservative. British work (Chalmers *et al.*, 1999) suggests new high yielding wheat crops could be removing 15 kg Mg in the grain and straw but more importantly could have a maximum uptake at the soft dough stage of 30-35 kg Mg/ha. In the late spring in 1999 and to some degree 1998, Mg deficient symptoms were quite common in Mid Canterbury. Cereal crops typically showed pale striping often accompanied by light green or yellow beading down the blade of mid to older leaves when

held up to the light. Acid soil conditions can also contribute to the problem (Castleman *et al.*, 1998).

On a previous occasion when Mg deficiency like leaf symptoms were noted, staff of Pyne, Gould, Guinness screened a range of proprietary liquid products as single sprays on winter wheat, applied at the late vegetative stages. These were also compared against solid Epsom salt. No product tested satisfactorily raised herbage magnesium levels one and four weeks after spraying, and after four weeks no symptoms were evident in the control crop (M. Kelly pers. comm.).

A better option to avoid deficiency symptoms in cereals may be to lift soil Mg levels. On pasture soils it is not difficult to Mg lift levels in Yellow Brown Loams – Allophanic soils (McNaught *et al.*, 1973) and in Recent and local Yellow Brown Earths – Pallic soils (Craighead, unpublished; Strachan pers. comm.). The choice and timing of products is important. Epsom salt is now seldom used as a solid fertiliser as it is considered too soluble, particularly for autumn application. Kieserite, which has anecdotally been used with some success in kale seed in Mid Canterbury, is widely used in European cropping (Haedter pers. comm.). Draycott *et al.* (1975) have shown kieserite to give yield increases in sugar beet. Magnesium oxide is widely used in New Zealand, as it is the most cost effective Mg fertiliser. However it may act too slowly for crops so timing of application may be important.

A more extensive review of Mg in cropping is provided in the preceding paper in this volume (Craighead, 2001a).

The objective of this research was to compare different rates of two solid Mg fertiliser products applied to a wheat crop in the autumn with spring applied magnesium fertilisers, including a liquid spray, as a means of increasing the herbage Mg content and hence the yield and quality of a wheat crop.

Materials and Methods

Site

Three sites to be sown in autumn sown wheat were selected near Methven on the basis of their low soil Mg levels (QTMg 3-4). The sites were; Grants just outside Methven, on Ruapuna and Mayfield silt loams, previously in borage; and two sites, Ridges and Wrights, NE of Methven towards the Rakaia River, on Lyndhurst silt loams following run-out pasture and white clover seed crops respectively. All three sites had stony topsoil and were reliant on rainfall for moisture. Base fertility (bar Mg) was good at Grants and Ridges but P levels were slightly low (Olsen P 13) at Wrights. Soil pH was adequate for wheat production. All sites received phosphorus at planting and N and plant protection measures were applied in accordance with normal farmer practice.

The trial was laid down as a randomised block design with four replicates at each site. Plot size was 1.8 m x 10 m. These were marked out after crop emergence when autumn treatments were applied; further soil Mg tests were taken and plant populations were measured. Magnesium treatments are given in Table 1.

8.	Spring	Kieserite	22.5
9.	Spring	Magnesium oxide	90
10.	Spring	Magflo	0.9

*two applications of 1.5 l/ha at 14 days apart

Kieserite (granular magnesium sulphate monohydrate) contains 15%Mg and was imported from Kali and Salz, Germany. Magnesium oxide (fertiliser grade calcined magnesite) contains 52%Mg and was imported from China. Magflo is a fluid magnesium oxide suspension, 30%Mg, produced by Agrichem Manufacturing Industries Ltd., Australia. All three are marketed by Ravensdown Fertiliser Co-op Ltd. Spring application rates were dictated by cost and label application rates.

Treatments were applied and herbage was sampled at different times at each site to match crop maturity. Spring treatments were applied after the first herbage sampling at 1st node and the second herbage sampling taken at or just after booting, in late November. Grain was harvested in mid February. Full details are given in Table 2.

Soil and herbage samples (whole above ground plant) were sent to Analytical Research Laboratories Limited (ARL), Napier for Mg analysis. Plots were harvested using a plot header and sub samples kept for grain weight and screenings with further grain sent to ARL for grain N and Mg determination.

Data were analysed with analysis of variance. Contrasts between treatments were made within the analysis.

Results

Rainfall data (Table 3) indicated that soil moisture was unlikely to be a severe restriction to growth. The Grant site (Methven) had slightly better spring rainfall than the Ridge (Greenfield) site.

All three sites had slightly patchy emergence. Plant populations were highest at Grants, (171 plants/m²)

and more advanced and taller on any given date due to the earlier sowing date. Some weed spray drift damaged two replicates early in the season and stunted plants. Ridge's crop had a population of 140-150 plants/m² and had patches of poor growth throughout the trial. This damage was attributed to grass grub and delayed development of those plants in the spring. Wright's crop had a population of 136 plants/m² and looked thin but without any apparent cause. Although these plant populations appear low compared to traditional New Zealand plant populations, they are typical of those recommended for these new British bred cultivars.

There were no visible signs of Mg deficiency or a Mg fertiliser response in terms of height or colour, at any of the three sites.

Table 3. Rainfall at Methven (Grants) and Greenfields (Ridges)⁺.

Month	Methven	Greenfields
April (from 14 th)	75	-
May	75	23 (from 23 rd)
June	32	60

At the first herbage sampling, increasing the rate of kieserite applied in autumn produced significantly increasing ($p < 0.01$) Mg levels in the herbage, with up to 29% more Mg than in the control at the Ridge site. The greatest responses were seen at this site. All other treatments produced similar Mg levels to the control with the exception of a 12% response at Ridges to 90 kg Mg as magnesium oxide in the autumn (Table 5).

At the second herbage sampling, there was generally no significant effect of the treatments on herbage Mg, although the same pattern of increasing herbage Mg with increasing rates of autumn applied kieserite occurred at Ridges and Wrights. At Wrights this was a significant ($p < 0.05$) effect (Table 6).

Grain yield was high at Grants averaging 10.6 t/ha with an average grain weight of 43 mg and 1.4% screenings. Ridges (6.6 t/ha) and Wrights (7.1 t/ha) were lower yielding with lower grain weights (34.4 mg and 36.6 mg respectively) and higher screenings (both 2.9%; Tables 4, 5 and 6).

At Grants and Wrights there was no effect of Mg fertiliser on grain yield, grain weight or screenings. At Ridges there was some evidence ($p < 0.05$) of an increase in grain weight over the control for the spring Mg treatments but there was no effect of form of Mg in

the spring. This did not result in increased yield (Table 5).

There was no significant effect of Mg fertiliser treatment on % N or % Mg in the grain. Average concentrations of N and Mg at each site were, Grants 1.82% N and 0.076% Mg, Ridges 1.90% N and 0.064% Mg, and Wrights 1.80% N and 0.069% Mg.

Magnesium uptake in the grain was low and varied from 4 kg Mg/ha at Ridges to 8 kg Mg/ha at Grants.

Discussion

Yields

Yields of Buster (Ridge and Wright sites) were similar to the four-year average for Methven (FAR, 2000) but much lower than the 2000 season average for this cultivar. Historically, Buster has slightly outyielded Hussar at Methven (Grant site). Both are true English wheat and require winter vernalisation to maximise yields (FAR, 2001) so the month later sowing date would also have reduced Buster yields at Ridges and Wrights. Grants site is a heavier soil receiving more consistent rain and therefore is capable of higher yields. The lower plant populations and plant establishment in cooler conditions did not help the

crops at the Ridge and Wright sites, made worse by the early grass grub damage at Ridges.

Herbage Standards

In all instances, control Mg levels were below the optimum 0.15% recommended by Reuter and Robinson (1998) and at times below the 0.11-0.12% typically found in New Zealand wheat crops (Craighead, 1999). There are reports that Mg deficiency symptoms may not be noted until levels fall to 0.09-0.10% and it is not clear whether yield is even affected when levels drop to 0.08% (Scott and Robson; 1991, M. Carver pers. comm.). The results here would support these conclusions. It is interesting that on the two lowest Mg sites herbage levels decreased quite dramatically between herbage samplings whereas at the Grant site they actually increased. Reasons for this could be that the earlier sowing at Grants enabled deeper rooting and more accessibility to subsoil Mg, and that Hussar was better able to utilise Mg than was Buster. The previous monitoring of the ACE trials (Craighead, 1999) shows that over a range of cultivars the herbage Mg content in healthy crops is generally maintained through the spring, and if anything slightly improves, up to ear emergence.

Magnesium cost and release

The results suggest kieserite is the best magnesium product to use to lift herbage levels, as previously suggested by Haerdter (pers. comm.) and Draycott *et al.* (1975). While Draycott *et al.* (1975) found kieserite effective in spring; this work suggests kieserite should be applied in autumn or early winter if soil testing shows low magnesium levels. Epsom salts, which was not tested, would likely be a better spring proposition as it is much more soluble, although it is not very cost effective. Magnesium oxide is a more cost effective product than kieserite as it is three times as concentrated and slightly cheaper per tonne of product. This means more product could be used to partly offset its slower availability of Mg, although in these trials this was only really apparent on the most responsive site, Ridges. Over time the remaining Mg would have also become plant available, so we would anticipate soil magnesium levels would have been higher for the next crop where 90 kg/ha of MgO was used in comparison to 22.5 kg/ha of kieserite.

In this trial the fertilisers were broadcast after plant establishment. If autumn treatments were incorporated into the soil prior to planting the extra time and reactivity within the soil should hasten Mg release. This would further make high rates of magnesium oxide in autumn a viable option, especially if one aim was to raise the base fertility for future farming. However Haerdter (pers. comm.) suggests kieserite does not need to be soil incorporated to work effectively. The trial results suggest that even if Mg deficiency symptoms were already noted before a problem with magnesium was identified, foliar application of magnesium is unlikely to be effective in solving the problem. This supports the previous conclusions by PGG (M. Kelly pers. comm.). Sprays only provide a small amount of Mg and given that Mg is a macro-element and is required in reasonable amounts, foliar applications will at best only be of short-term benefit.

Soil and climatic conditions

Symptoms of magnesium deficiency were not observed in the spring of 2000, despite soil Mg levels being very low, especially at Ridges. The New Zealand pastoral data and English cropping data would have suggested that all three sites would be responsive to magnesium. While magnesium deficiency can be present at the levels encountered, Archer (1998) suggested that cereals might not respond to Mg until levels get as low as 15 mg/l (approx QTMg 3). This does not adequately explain why symptoms have been observed in other seasons at higher soil Mg levels.

Data from Winchmore Research Station show that the spring of 2000 was warmer and wetter than 1998 and 1999, and this led to ideal spring growth. Slightly cooler weather in October and November continued this pattern and delayed the rapid transition to hot, dry summer conditions. In contrast, in particular in 1999 and to some degree 1998, early growth was intermittent because of cool conditions. Magnesium deficiency symptoms were not widespread in 2001 despite a cool but dry spring, probably because the season remained cool but wet until the New Year and rapid growth changes did not occur.

The use of nitrogen through this period would also impact differently on magnesium uptake. The warm, adequate moisture conditions in 2000 would have aided magnesium uptake, as most N would have been

taken up in the nitrate form. By contrast in the 1998 and 1999 seasons, the cooler temperatures generally coupled with damp conditions meant that nitrogen was more likely to remain in the ammonium form for longer and so compete with magnesium for uptake (Mulder, 1956). The apparent transient nature of Mg leaf symptoms could equally be explained by the fact that at the end of crop vegetative growth, soil temperatures are sufficiently warmer and soils drier which will enhance Mg uptake. In addition, roots are presumably deeper and better able to forage for Mg. These Yellow Grey Earths may have better exchangeable subsoil Mg compared to topsoil Mg, a feature of many of these soils (Metson and Brooks, 1975). It is also likely that maximum magnesium uptake had occurred by this point since herbage Mg levels in healthy crops still remained near their peak of 0.11-0.16% Mg.

In summary, given that spring climatic conditions appear to dictate whether symptoms are likely to occur and that these can occur over a range of soil magnesium levels (up to QTMg 10), it is impossible to predict whether Mg deficiency symptoms are likely to occur. The effect on final crop yield is still unknown, but may be less than initially thought, given that other crops such as potatoes and brassica seed crops grown on the farm may be more responsive to magnesium. If stock performance is likely to suffer at low soil and plant magnesium levels, then the simplest way to overcome potential magnesium deficiency in wheat may be to lift the base fertility of the farm. This would allow the use of cheaper forms of magnesium (e.g., magnesium oxide) as autumn maintenance dressings or, if liming is also required, dolomite (10% Mg).

Conclusions

Kieserite applied in the autumn was effective in increasing herbage Mg content at four of the six samplings, but the effect did not carry through to grain yield or quality. The other Mg fertiliser treatments had no significant effect on herbage Mg content or on grain yield or quality. The results suggest that applying Mg fertilisers to wheat to increase yield or quality may not be justified.

However, the problem of Mg deficiency in wheat is seasonal and in seasons where symptoms are more widespread (this has occurred in at least two of the last

four seasons, 1998/99 –2001/02), kieserite in autumn may have been justified.

Further, application of Mg fertilisers to wheat may be justified in order to improve soil Mg status for subsequent crops that are more sensitive to low soil Mg levels, and for pasture where low herbage may affect animal performance. Assuming these crops and pasture behave similarly to wheat then the Mg should be applied in the autumn to be effective.
